Chapter 1

Introduction to Ordinary Differential Equations

Differential equations come from real-world problems and problems in applied mathematics. When mathematics is applied to real-world problems, it is often the case that finding a relation between a function and its rate of change is easier than finding a formula for the function itself; it is this relation between an unknown function and its derivatives that produces a differential equation.

To give a very simple example, a biologist studying the growth of a population with size at time t given by the function $P(t)$, might make the very simple, but logical, assumption that a population grows at a rate directly proportional to its size. In mathematical notation, the equation for $P(t)$ could then be written as:

$$\frac{dp}{dt} = rP(t) \tag{1.1}$$

Where the constant of proportionality, r would probably be determined experimentally by biologists working in the field. Equations used for modeling population growth can be much more complicated than this, sometimes involving scores of interacting populations with different properties.

§1.1 Basic Terminology

> **Definition 1.1.1**
>
> differential equation is any equation involving an unknown function and one or more if its derivatives.

The following are examples of differential equations:

1. $P'(t) = rP(t)(1 - P(t)/N) - H$ harvested population growth

2. $\frac{d^2x}{d\tau^2} + 0.9\frac{dx}{d\tau} + 2x = 0$ spring mass equation

3. $I''(t) + 4I(t) = sin(\omega t)$ RCL circuit showing beats

4. $y''(t) + \mu(y^2(t) - 1)y'(t) + y(t)$ ban der Pol equation

5. $\frac{\partial^2}{\partial x^2}u(x, y) + \frac{\partial^2}{\partial y^2}u(x, y) = 0$ Laplace's equation

§1.1.1 Ordinary vs. Partial Differential Equations

Differential equations fall into two very broad categories, called ordinary differential equations and partial differential equations. If the unknown function in the equation is a function of only one variable, the equation is called an ordinary differential equation. If

the unknown function in the equation depends on more than one independent variable, the equation is called a partial differential equation, and in this case, the derivatives appearing in the equation will be partial derivatives.

§1.1.2 Independent Variables, Dependent Variables, and Parameters

Three different types of quantities can appear in a differential equation. The unknown function, for which the equation is to be solved, is called the dependent variable, and when considering ordinary differential equations, the dependent variable is a function of a single independent variable. In addition to the independent and dependent variables, a third type of variable, called a parameter, may appear in the equation. A parameter is a quantity that remains fixed in any specification of the problem, but can very from problem to problem.

§1.1.3 Order of a Differential Equation

Another important way in which differential equations are classified is in terms of their order.

Definition 1.1.2

he order of a differential equation is the order of the highest derivative of the unknown function that appears in the equation.

The differential equation 1 is a first-order equation and the others are all second-order. Even though equation 5 is a partial differential equation, it is sitll said to be of second order since no derivatives of order higher than two appear in the equation.

§1.1.4 What is a solution

Given a differential equation, what is a solution? We must realize that we are looking for a function, and therefore it needs to be defined on some interval of its independent variable.

Definition 1.1.3

n analytic solution of a differential equation is a sufficiently differentiable function that, if substituted into the equation, together with the necessary derivatives, makes the equation an identity (a true statement for all values of the independent variable) over some interval of the independent variables.

Problem 1. *Show that the function $p(t) = e^{-2t}$ is a solution to the differential equation:*

$$x'' + 3x' + 3x = 0 \tag{1.2}$$

Solution. To show that it is a solution, compute the first and second derivatives of $p(t)$:

$$p'(t) = -2e^{-2t} \tag{1.3}$$

$$p''(t) = 4e^{-2t} \tag{1.4}$$

When the three functions $p(t)$, $p'(t)$, and $p''(t)$ are substituted into the differential equation in place of x, x', and x'', it becomes:

$$(4e^{-2t}) + 3(-2e^{-2t}) + 2(e^{-2t}) \equiv 0 \tag{1.5}$$

$$(4 - 6 + 2)(e^{-2t}) \equiv 0 \tag{1.6}$$

$$(0)(e^{-2t}) \equiv 0 \tag{1.7}$$

which is an identity (in the independent variable t for all real values of t). When showing that both sides of an equation are identical for all values of the variables, we will use the equivalence sign $\equiv$.

Problem 2. Show that the function $\phi(t) = (1 - t^2)^{1/2} \equiv \sqrt{1 - t^2}$ is a solution of the differential equation $x' = -t/x$.

Solution. First, notice that $\phi(t)$ is not even defined outside of the interval $-1 \le t \le 1$. In the interval $-1 < t < 1$, $\phi(t)$ can be differentiated by the chainr ule (for powers of functions):

$$\phi'(t) = \frac{1}{2}(1 - t^2)^{-\frac{1}{2}}(-2t) = -\frac{t}{(1 - t^2)^{\frac{1}{2}}} \tag{1.8}$$

The right-hand side of the equation $x' = -t/x$, with phi(x) substituted for x, is

$$-\frac{t}{\phi(t)} = -\frac{t}{(1 - t^2)^{\frac{1}{2}}} \tag{1.9}$$

which is identically equal to $\phi(t)$ wherever ϕ and ϕ' are both defined. Therefore, $\phi(t)$ is a solution to the differential equation $x' = -t/x$ on the interval (-1, 1).

§1.2   Systems of Differential Equations

Problem 3. Show that the functions $x(t) = e^{-t}, y(t) = -4e^{-t}$ form a solution of the system of differential equations

$$x'(t) = 3x + yy'(t) = -4x - 2y \tag{1.10}$$

Solution. The derivatives that we need are $x'(t) = -e^{-t}$ and $y'(t) = -(-4e^{-t}) = 4e^{-t}$. Then substitution into the second equation gives:

$$3x + y = (2e^{-t}) + (-4e^{-t}) = (3 - 4)e^{-t} = -e^{-t} \equiv x'(t), \tag{1.11}$$

$$-4x - 2y = -4(e^{-t}) - 2(-4e^{-t}) = (-4 + 8)e^{-t} = 4e^{-t} \equiv y'(t); \tag{1.12}$$

therefore, the given functions of x and y form a solution for the system.

§1.3   Families of Solutions, Initial-Value Problems

In this section the solutions of some very simple differential equations will be examined in order to give us an understanding of the terms *n*-parameter family of solutions and general solution of a differential equation. We will also be shown how to use certain types of information to pick one particular solution out of a set of solutions.

   While we do not yet have any formal methods for solving differential equations, there are some very simple equations that can be solved by inspection. One of these is:

$$x' = x \tag{1.13}$$

   This first-order differential equation asks you to find a function $x(t)$ which is equal to its own derivative at every value of t.

Definition 1.3.1

first-order differential equation with one initial condition specified is called an initial-value problem, usually abbreviated as an IVP. The solution of an IVP will be called a particular solution of the differential equation.

Problem 4. *Solve the IVP $x' = x, x(0) = \frac{1}{2}$.*
   Solution. Since we just found that the general solution of $x' = x$ is $x(t) = Ce^t$, we only need to use the initial condition to determine the value of C. This will pick out one particular curve in the family. Substituting $t = 0$ and $x(0) = \frac{1}{2}$ into the general solution,

$$x(0) = Ce^0 = C = \frac{1}{2}. \tag{1.14}$$

   With $C = \frac{1}{2}$, the solution of the IVP is $x(t) = \frac{1}{2}e^t$. This particular solution is the dotted curve shown in Figure 1.1, with the initial point $(0, \frac{1}{2})$ circled.

Chapter 2

First-Order Differential Equations

In this chapter, methods will be given for solving first- order differential equations. First-order means that the first derivative of the unknown function is the highest derivative appearing in the equation. This implied that the most general first-order differential equation has the form $F(t, x, t') = 0$ for some function F, in this chapter, we will assume that the equation can be solved explicitly for x'. This means that our first-order differential equations can always be put in the form:

$$x' = f(t, x) \tag{2.1}$$

where f denotes an arbitrary function of two variables. To see why such an assumption makes sense, supposed the differential equation is:

$$(x'(x))^2 + 4x'(t) + 3x(t) = t. \tag{2.2}$$

It would be messy, but not impossible to use the quadratic formula to extract two differential equations of the form $x' = f(t, x)$ from this quadratic equation. However, one could also imagine equations where solving for $x'(t)$ is not even possible, and in such a case, some of our methods might not be applicable.

The material in this chapter will cover several analytic methods for solving first-order differential equations, each requiring the function f to have a special form. Two different graphical methods are also described; one for the general equation depending only on x. Numerical methods for first-order equations are introduced and theoretical issues of existence and uniqueness of solutions are discussed.

§2.1   Separable First-Order Equations

The first analytic method we will consider applies to first-order equations that can be written in the form

$$\frac{dx}{dt} = g(t)h(t); \tag{2.3}$$

that is, when the function $f(t, x)$ can be factored into a product of a function of t times a function of x. Such a differential equation is called separable.

Problem 5. *Determine which of the following first-order differential equations are separable. Hint: try to factor the right- hand side if the equation does not initially appear to be separable.*

$$x' = xt + 2x \rightarrow x' = x(t + 2) \rightarrow g(t) = t + 2, h(x) = x \tag{2.4}$$

$$x' = x + \cos(t) \tag{2.5}$$

$$x' = xt^2 + t^2 - tx \rightarrow x' = (t^2 - t)(x + 1) \rightarrow g(t) = (t^2 - t), h(x) = (x + 1) \tag{2.6}$$

$$x' = x^2 + x + 3 \rightarrow x' = (1)(x^2 + x + 3) \rightarrow g(t) = 1, h(x) = x^2 + x + 3 \tag{2.7}$$

1. *If $h(x) = 1$, the separable equation $x' = g(t)$ is just an integrating problem and the solution is*

$$x = \int g(t)dt; \tag{2.8}$$

   that is, x is just the **indefinite integral** of the function $g(t)$. Remember that this means that x can be *any* function $G(t)$ such that $G'(t) = g(t)$, and this introduces an arbitrary constant into the solution. As an example, the solution of $x' = t + 1$ is

$$x(t) = \int (t + 1)dt = \frac{t^2}{2} + t + c \tag{2.9}$$

   Even in this simple case the solution is an infinite one-parameter family of functions.

2. *If $g(t) = 1$, the separable equation $x' = h(x)$ is called an **autonomous** first-order differential equation. Unless $h(x)$ is a constant, it is no longer possible to solve the equation by simple integration, and the method given below must be used. Autonomous first-order differential equations are important and will be investigated more thoroughly in section 2.7. In the above examples, only the last equation is autonomous. The other three contain functions of t (other than the unknown function $x(t)$) on the right-and side.*

Problem 6. *Solve the differential Equation $\frac{dx}{dt} = -tx^2$.*
   Solution. Split dx/dt into two pieces, dx and dt, and do a bit of algebra to write:

$$-\frac{dx}{x^2} = tdt \tag{2.10}$$

Integrate each side with respect to its own variable to obtain:

$$\int \left(-\frac{1}{x^2} \right) = \int tdt \rightarrow \frac{1}{x} = \frac{t^2}{x} + C. \tag{2.11}$$

where the arbitrary constants on each side have been collected on the right. Solve this equation for x to obtain the one parameter family of solutions

$$x = \frac{1}{(t^2/2) + C}. \tag{2.12}$$

We should check that the function $x(t)$ does satisfy the differential equation for any value of the constant C. It appears that this method works, but splitting dx/dt into

two pieces is not a mathematically condoned operation; therefore, a justification of the method needs to be given.

If an equation is separable, and $x'(t)$ is written as dx/dt, both sides of the equation $dx/dt = g(t)h(x)$ can be divided by $h(x)$, and the equation becomes

$$\frac{1}{h(x(t))}\left(\frac{dx}{dt}\right)dt = \int g(t)dt + C. \tag{2.13}$$

The method of simple substitution can be applied to the integral on the left. If we substitute $u = x(t)$, then $du = (dx/dt)dt$, and the equation becomes

$$\int \frac{1}{h(u)}du = \int g(t)dt + C. \tag{2.14}$$

Now let $H(u)$ be any function such that $H'(u) = 1/h(u)$ and $G(t)$ any function with $G'9t) = g(t)$. Then the equation above implies that

$$H(u) + C_1 = G(t) + C_2 \rightarrow H(u) = G(t) + C, \tag{2.15}$$

Where C is the constant $C_2 - C_1$
Replacing u again by $x(t)$:

$$H(x(t)) = G(t) + C \tag{2.16}$$

Check carefully that the expression $H(x) = G(t) + C$ is exactly the same as the solution obtained above. It is an **implicit solution** of $-dx/x^2 = tdt$; that is, it defines a relationship between the unknown function x and its independent variable t. If it can be solved explicitly for x as a function of t, the result is called an **explicit solution of the differential equation. As expected, the integration produces an infinite on-parameter family of solutions

---

Theorem 2.1.1

To solve a separable first-order differential equation, $x'(t) = g(t)h(x)$:

- Write the equation in the form $dx/dt = g(t)h(x)$.

- Multiply both sides by dt, divide by $h(x)$, and integrate, to put the equation in the form

$$\int \frac{1}{h(x)}dx = \int g(t)dt. \tag{2.17}$$

- Find any function $H(x)$ such that $H'(x) = 1/h(x)$ and any function $G(t)$ such that

- Write the solution as $H(x) = G(t) + C$

- If possible, solve the equation from the previous step explicitly for x, as a function of t.

§2.2

§2.3

§2.4 Existence and Uniqueness of Initial Value Problems

Given an initial value problem, how can I know that a solution exists, and if so, the uniqueness of that solution.

Problem 7. $\frac{dx}{dt} = \sqrt{x}$, $x(0) = 0$ *has two solutions. These solutions are* $x(t) = \frac{t^2}{4}$ *and* 0. *We can change the initial condition to be* $x(0) = 5$. *we can separate our values to get:*

$$x(t) = \left(\frac{t}{2} + \sqrt{5} \right)^2 \tag{2.18}$$

If we change the initial condition to $x(5) = -5$ *we get no solutions. We can also change the initial condition to* $x(5) = 0$ *which gives us two solutions:*

$$x(t) = \left(\frac{t-5}{2} \right)^2 \tag{2.19}$$

$$x(t) = 0 \tag{2.20}$$

§2.5 Exact Ordinary Differential Equations

This highlights an analytic technique to find the solutions to an ordinary differential equation. This technique depends on if we are able to write an ODE in the form $\frac{d}{dx}(F(x, y(x))) = 0$. How can we tell if this is possible?

We can determine this by using the multi-variable chain rule from calculus 3:

$$\frac{d}{dx}(F(x, y(x))) = \frac{\partial F}{\partial x} + \frac{\partial F}{\partial y}\frac{dy}{dx} = 0 \tag{2.21}$$

Now in order to actually solve the ordinary differential equation, we will turn the equation above into something that we can work with:

$$M(x, y) + N(x, y)\frac{dy}{dx} = 0 \tag{2.22}$$

Now we ask the question, does $f(x, y)$ exist such that $\frac{\partial F}{\partial x} = M(x, y)$ and $\frac{\partial F}{\partial y} = N(x, y)$? We can test this by checking to see if we can do the following:

$$\frac{\partial^2 F}{\partial x \partial y} = \frac{\partial^2 F}{\partial y \partial x} \rightarrow \boxed{\frac{\partial M}{\partial y} = \frac{\partial N}{\partial x}} \tag{2.23}$$

If it passed the test, we use the equations to find $F(x, y)$, and then we can use $F(x, y(x)) = C$ to find the solution to the problem.

Problem 8. *Calculus 3 example. Consider a field $\vec{v} =< 2y + 4x, 2x - 5y >$. Is this a gradient field? If so, what is its potential function. In order to find this, there must be a function $f(x, y)$ such that $\triangledown f = \vec{v}$.*

$$\partial f \partial y\rangle =< 6xy, 2x - 5y > \tag{2.24}$$

$$\frac{\partial f}{\partial x} = 6xy, \qquad\qquad \frac{\partial f}{\partial y} = 2x - 5y \tag{2.25}$$

Therefore, we know that $f_{xy} = f_{yx}$ Now we just need to set the two equations equal to each other and solve:

$$\frac{\partial}{\partial y}(2y + 4x) \stackrel{?}{=} \frac{\partial}{\partial x}(2x - 5y) \tag{2.26}$$

And we can solve that equation algebraicly and get $2 = 2$, therefore this is the solution to the ordinary differential equation

Problem 9. *Solve $(4x + 2y) + (2x - 5y)\frac{dy}{dx} = 0$. We should set $M(x, y) = 4x + 2y$ and set $N(x, y) = (2x - 5y)$.*

1. *Testing to see if $\frac{\partial M}{\partial y} = \frac{\partial N}{\partial x}$*

$$\frac{\partial}{\partial y}(4x + 2y) \stackrel{?}{=} \frac{\partial}{\partial x}(2x - 5y) \tag{2.27}$$

2. *Now we need to find $F(x, y)$:*

$$\frac{\partial F}{\partial x} = 4x + 2y \qquad\qquad\qquad \frac{\partial F}{\partial y} = 2x - 5y \tag{2.28}$$

$$F(x, y) = \int (4x + 2y)dx = 2x^2 + 2xy + c_y, \quad F(x, y) = \int (2x - 5y)dy = 2xy - \frac{5}{2}y^2 + c_x \tag{2.29}$$

We can determine that $c_y = \frac{5}{2}y^2$ and $c_x = 2x^2$ by looking at the two equations next to each other. Therefore, we know that $F(x, y) = 2x^2 + 2xy - \frac{5}{2}y^2$.

Our resulting solution is:

$$\boxed{2xy - \frac{5}{2}y^2 + 2x^2 = C} \tag{2.30}$$

This was an implicitly defined solution, so $F(x, y) = 2xy - \frac{5}{2}y^2 + 2x$, and our ode is:

$$\frac{d}{dx}\left[2xy(y) - \frac{5}{2}(y(x))^2 + 2x^2\right] = \frac{d}{dx}[C] \tag{2.31}$$

$$(2y + 2xy') - \frac{5}{2}2(y) + 4x = 0 \tag{2.32}$$

$$\tag{2.33}$$

Example 2 *Solve the differential equation,*

$$2x^2y + e^y + (x^3 + xe^y - 2y)\frac{dy}{dx} = 0. \tag{2.34}$$

We can see that $3x^2y + e^y = M(x,y)$ and $(x^3 + xe^y - 2y)\frac{dy}{dx} = 0$.
We can test this by checking to see if:

$$\frac{\partial M}{\partial y} \overset{?}{=} \frac{\partial N}{\partial x} \tag{2.35}$$

and by taking the partial derivatives of each of the equations, we can see that $3x^2 + e^y = 3x^2 + e^y$. Now that we know that this is an exact ordinary differential equation, we need to solve for $F(x,y)$. In order to find $F(x,y)$, we must do

$$\frac{\partial F}{\partial x} = M \qquad\qquad \frac{\partial F}{\partial y} = N. \tag{2.36}$$

This means that

$$F(x,y) = \int (3x^2y + e^y)dx \qquad F(x,y) = \int (x^3 + xe^y - 2y)dy \tag{2.37}$$

$$= x^3y + xe^y + C_y \qquad\qquad = x^3y + xe^y - y^2 + C_x \tag{2.38}$$

$$\tag{2.39}$$

So, $F(x,y) = x^3yxe^y - y^2$, and our solution is:

$$\boxed{x^3y + xe^y - y^2 = C} \tag{2.40}$$

Now we need to find a solution that satisfies the initial value proble, $y(-2) = 1$.

$$(-2)^3(1) + (-2)e^1 - (1)^2 = C \tag{2.41}$$

$$-8 - 2e - 1 = C \tag{2.42}$$

$$-9 - 2e = C \tag{2.43}$$

$$\tag{2.44}$$

Which results in our particular solution being:

$$\boxed{x^3y + xe^y - y^2 = -9 - 2e} \tag{2.45}$$

§2.5.1 Substitution

Sometimes we can make a substitution that turns one ordinary differential equation into one that we can solve.

Problem 10. *Let's take the equation $\frac{dy}{dx} = \frac{1-x-y}{x+y}$. In order to do this you need to trade out $y(x)$ for $u(x)$:*

$$\frac{dy}{dx} = \frac{du}{dx} - 1 \tag{2.46}$$

$$\frac{du}{dx} - 1 = \frac{1-u}{u} = \frac{1}{u} - 1 \tag{2.47}$$

After we do those steps, we can see that this is a separable ordinary differential equation, and we can use the normal method to solve a separable equation:

$$\int u\,du = \int 1\,dx$$

$$\frac{u^2}{2} = x + C$$
$$u^2 = 2x + D \leftarrow D = 2C \tag{2.48}$$
$$(x+y)^2 = 2x + D \rightarrow x + y = \pm\sqrt{2x+D}$$
$$y = -x \pm \sqrt{2x+D}$$

Where the initial condition determines the last equation above. Now we need to solve for the initial condition of $y(6) = 4$, and we can do this by just pluggin in the values, and determining the sign on the square root:

$$4 - 6 \pm \sqrt{12+D}$$
$$10 = \pm\sqrt{12+D} \tag{2.49}$$
$$D = 88 \rightarrow y(x) = -x + \sqrt{2x+88}$$

§2.5.2 Bernoulli Ordinary Differential Equations

We use Bernoulli's solution to an ordinary differential equation if the equation can be written in the form $\frac{dx}{dt} + p(t)x = q(t)x^n$, where if $n = 0$, the equation is linear and where if $n = 1$, the equation is both linear and separable. We can do a substitution for Bernoulli ordinary differential equations where we let $v = x^{1-n}$, and we trade out $x(t) \rightarrow v(t)$ to turn the differential into a linear differential. Another formula we can use for pluggin in to find the separable ordinary differential equation is $\frac{du}{dx} + (1-n)p(x)u = (1-n)q(x)$, but we do not have an example to show for that method.

Problem 11. *Consider the Ordinary differential equation $t\frac{dy}{dt} + y = \frac{1}{y^2}$, and solve. Our first step for this problem is to divide both sides by t to rearrange it into the Bernoulli form:*

$$\frac{dy}{dt} + \frac{1}{t}y = \frac{1}{t}y^-2 \tag{2.50}$$

Because y is our dependent variable, we will be looking for our n value, and we will find it on the y on the right hand side. This gives us $n = -2$. Now we need to let $v(t) = y^{1-(-2)} = y^3$ and this means that $y(t) = (v(t))^{1/3}$. Now wee need to take the differential of this equation in order to find a substitution for $\frac{dy}{dt}$:

$$\frac{dy}{dt} = \frac{1}{3y^2}\frac{dv}{dt} \tag{2.51}$$

$$\frac{dv}{dt} = 3y^{-2}\frac{dy}{dt} \tag{2.52}$$

$$\tag{2.53}$$

Once we have found a substitution for $\frac{dy}{dt}$, we can simply plug in our equation and solve for $v(t)$:

$$\frac{1}{3y^2}\frac{dv}{dt} + y = \frac{1}{y^2} \tag{2.54}$$

$$\frac{t}{3}\frac{dv}{dt} + y^3 = 1 \tag{2.55}$$

We solve for $v(t)$ and then we can use the integrating factors method to solve the ordinary differential equation:

$$\begin{aligned}
\frac{dv}{dt} + \frac{3}{t}v &= \frac{3}{t} \\
\mu(t) = e^{\int \frac{3}{t}dt} &= e^{3ln(t)} = t^3 \\
t^3\frac{dv}{dt} + 3t^2 v &= 3t^2 \\
\frac{d}{dt}(t^3 v) &= 3t^2 \\
\int t^3 v = \int 3t^2 dt &= t^3 + C \\
v(t) = 1 + \frac{C}{t^3} &\to y(t) = (v(t))^{\frac{1}{3}}
\end{aligned} \tag{2.56}$$

Now we just need to let $v(t) = y^3$ and plug this back into the equation to get $y(t) = \left(1 + \frac{C}{t^3}\right)^{\frac{1}{3}}$ as our final solution.

Homogenius ordinary differential equations can be written in the form $\frac{dx}{dt} = f\left(\frac{x}{t}\right)$. This means that if we just substitute v for $\frac{x}{t}$, we will turn the Homogenius equation into a separable ordinary differential equation.

Problem 12. *Consider the homogenius ODE, $(5y - 2x)\frac{dy}{dx} = 4x + 2y$. We can divide the $5y - 2x$ so we will end up with the equation*

$$\frac{dy}{dx} = \frac{4x + 2y}{5y - 2x} = \frac{4 + \frac{2y}{x}}{5\frac{y}{x} - 2} \tag{2.57}$$

The reason we can make this change is because we are dividing everything on the left side by x to get it in the form $\frac{y}{x}$. Our next step is to trade out $y(x)$ for $v(x)$:

$$\frac{4 + 2v}{5v + 2} = v + x\frac{dv}{dx} \tag{2.58}$$

Which we can further simplify into $\frac{dv}{dx} = \frac{1}{x}\left(\frac{4+2v}{5v-2} - v\right)$ .. Now, we are able to solve this as a separable ordinary differential equation:

$$\frac{dv}{dx} = \frac{1}{x}\left(\frac{4 + 4v - 5v^2}{5v - 2}\right)$$

$$\frac{5v - 2}{4 + 4v - 5v^2}dv = \frac{1}{x}dx \tag{2.59}$$

Now we need to let $u - 4 + 4v - 5v^2$, and let $du = (4 - 10v)dv = -2(5v - 2)dv$. And then we integrate with respect to u to end up with

$$-\frac{1}{2}\int \frac{1}{u}du = \int \frac{1}{x}dx$$

$$-\frac{1}{2}ln|u| = ln|x| + C$$

$$ln|4 + 4v - 5v^2| = -2ln|x| + D \tag{2.60}$$

$$4 + 4v + 5v^2 = e^{ln|x|^{-2}+D}$$

$$= e^{ln|x|^{-2}}e^{D}$$

$$4 + 4\left(\frac{y}{x}\right) - 5\left(\frac{y}{x}^2\right) = e^{ln|x|^{-2}}A$$

$$\boxed{4x^2 + 4xy - 5y^2 = A} \tag{2.61}$$

§2.6

§2.7 Phase Lines and Equilibrium Solutions

This is a qualitative technique for autonomous ordinary differential equations. This is used for finding the long term behavior of solutions for various initial conditions. An equilibrium solution is a constant function satisfying the ODE:

$$y(t) = k \rightarrow \frac{dy}{dt} = 0 \tag{2.62}$$

and we need to look for the roots of $f(y)$.

Problem 13. *Consider the ODE: $\frac{dy}{dx} = 4 - y^2$, we know that the equilibrium solutions (stationary points / fixed points / critical points) are $0 = 4 - y^2$ and $y = \pm 2$. If we were to plot this as a slope field, we would see an image like the following:*
We need to classify each of the lines here as stable (a sink), unstable (a source), or semi-stable (a node). From this slope diagram we can make a phase diagram.

The arrows in this diagram indiciate wether $\frac{dy}{dx}$ is above or below 0. We can see that the long term behavior of the solution:

$$y_0 = y(t_0) > 2, \rightarrow y(t) \rightarrow 2$$
$$-2 < 2_0, \rightarrow y(t) \rightarrow 2 \tag{2.63}$$
$$y_0 < -2, y(t) \rightarrow -\infty$$

Let's take a look at another example problem:

Problem 14. *Compare the pivots of the two ordinary differential equations, $\frac{dy}{dt} = y^2(1- y)^2$, and $\frac{dy}{dx} = y^2(1 - y^2)$.*
$$\frac{dy}{dt} = y^2(1 - y)^2 \qquad\qquad \frac{dy}{dt} = y^2(1 - y^2) \tag{2.64}$$
$$0 = y^2(1 - y)^2 \qquad\qquad 0 = y^2(1 - y^2) \tag{2.65}$$
$$y = 0, \pm 1 \tag{2.66}$$
$$\tag{2.67}$$

From finding the equilibrium points of the differential equations, we can now craft a pivot diagram:

From this we can see that in the long term, the equations are going to look like this:

$$y_0 < 0, y(t) \to 0 \tag{2.68}$$
$$0 < y_0 < 1, y(t) \to 1 \tag{2.69}$$
$$1 < y_0, y(t) \to \infty \tag{2.70}$$
$$\tag{2.71}$$

§2.7.1   Biforcations

For ordinary differential equations with a parameter, there are times that a small change in the value of the parameter results in a huge change in the behavior of the solutions. It causes a change in the number or stability of the equilibrium solutions.

Problem 15. *Find the biforcation value for*

$$\frac{dp}{dt} = 0.5p \left(1 - \frac{p}{100}\right) - H \tag{2.72}$$

The first step for finding a biforcation for an equation is finding the equilibrium solutions. In order to do that, we set equation (2.69) equal to 0 and then rearrange it so it is in the form

$$p^2 = -100p + 250H = 0 \tag{2.73}$$

In this case, we are going to need to use the quadratic formula to find the equilibrium points:

$$p = \frac{100 \pm \sqrt{10000 - 1000H}}{2} \tag{2.74}$$
$$= 50 \pm 5\sqrt{100 - 10H} \tag{2.75}$$
